It's about more than just CO₂
Aviation must reduce its **total impact** on climate

Aviation’s total climate impact is caused by more than just CO₂. Burning kerosene at altitude also generates contrails, induced cloudiness and NOx derivatives, that although short-lived, are estimated to contribute far more to global heating than all the accumulated aviation CO₂ to date. Even though this has been known for years, non-CO₂ impacts have been dismissed by industry, governments and the International Civil Aviation Organization (ICAO) as being too scientifically uncertain to warrant necessary action.

This has led to a public perception of aviation being a relatively small problem, a chronic lack of serious research and development to investigate solutions, and ineffective regulation of aviation’s climate impact¹. Non-CO₂ impacts are not accounted for in any reporting systems or regulations: the national greenhouse gases (GHG) inventory submissions to the UNFCCC; the Carbon Offsetting and Reduction Scheme for International Aviation (CORSIA), nor the EU Emissions Trading System (ETS). In addition, all current endeavours to “decarbonise” aviation disregard those impacts. Neither biofuels, synthetic fuels nor hydrogen would eliminate the main non-CO₂ contributors to global heating.

Mindful that non-CO₂ impacts constitute the majority of aviation’s climate heating impact and, unmitigated, prejudice against achieving of Paris Agreement goals and increase the risk of reaching climate system tipping points, it is important that they are fully acknowledged and that immediate action be taken to mitigate them.

Scientific research on aviation's climate impacts needs to be stepped up, but a recent study by 21 of the most renowned scientists in the field² has resolved important uncertainties that existed about the magnitude of the non-CO₂ impacts of aviation, and has set the ground for action. Further inaction by governmental regulators cannot be justified.

### THE FACTS

1. **Total Aviation-Caused Climate Heating is 3 Times That of CO₂ Alone.**

As stated by the IPCC already in 1999, persistent contrails and aviation induced cirrus (AIC), as well as NOx derivatives, although short-lived, contribute significantly more to global heating than aircraft CO₂ emissions alone. Aviation's contribution to today’s global heating, measured as Radiative Forcing (RF)³ from 1750 until today, has been estimated by the IPCC and the estimate is regularly updated by academic researchers.

In September 2020, 21 scientists prominent in the field published a reassessment taking into account the Effective Radiative Forcing (ERF) of non-CO₂ components. Their study concludes that today’s total climate impact of aviation is about 3 times greater than the impact alone of all the accumulated CO₂ emitted by aircraft and remaining in the atmosphere since flying began. This effective radiative forcing, caused by the accumulated CO₂ together with the short-lived non-CO₂ components which reappear everyday that flights continue, has contributed about 3.5% to the total anthropogenic global heating, one third from CO₂ and two thirds from non-CO₂.
The study also assessed the immediate and likely future impact of current aviation activity using a newly developed method that combines the heating effects of short-lived non-CO₂ contributors and long-lived CO₂. The researchers established that for the year 2018, total CO₂ emitted by aircraft was 1 Gt, while the non-CO₂ heating impacts represented the equivalent of emitting a further 2 Gt CO₂ that year. They concluded that “aviation emissions are currently warming the climate at approximately three times the rate of that associated with aviation CO₂ emissions alone”. In other words, a flight’s CO₂ impact must be tripled in footprint calculators, in GHG reporting systems and in national emissions inventories.

2. CURRENTLY (2018), FROM OIL WELL THROUGH FLIGHTS, AVIATION ACCOUNTS FOR 5.9% OF ALL HUMAN-INDUCED CLIMATE HEATING.

For years, the aviation industry claimed that the sector was responsible for only 2% of man-made carbon emissions – a number consistently cited to downplay the need for action. In fact, aviation’s CO₂ emissions alone are significantly higher – amounting to 2.4% of all human-caused carbon emitted globally in 2018 according to this latest study, and 2.9% in total when CO₂ emissions from the production and distribution of jet fuel are included. Then, adding on flying’s non-CO₂ climate impacts, we calculate that aviation’s on-going contribution reached 5.9% of the heating effect of all the annual human-caused greenhouse gas emissions in 2018.

This is immense, especially when considering that this impact is caused by a very small portion of people who actually fly: over 80% of the global population have never taken a flight while the top 10% of global income earners use 75% of air transport fuel.

3. CUTTING AIR TRAFFIC REDUCES NON-CO₂ CLIMATE IMPACTS IMMEDIATELY.

The need to multiply CO₂ emissions by 3 to account for non-CO₂ is a consequence of the strong growth of the traffic. If air traffic was steady, then fuel efficiency gains aside, the daily heating impact of short-lived contrail cirrus and NOx derivatives on the atmosphere would be largely constant, while the CO₂ would continue to accumulate and, even if all aviation were to cease, keep on heating for hundreds of years. Conversely, if air traffic were reduced, then the short-lived non-CO₂ impacts would similarly decrease and the reduction in heating would be equivalent to withdrawing large quantities of CO₂ from the atmosphere. Hence, any effort to reduce traffic, combined with measures to mitigate non-CO₂ impacts, will be extremely rewarding if these efforts are sustained.

4. TECHNICAL AND OPERATIONAL MITIGATION OF THE NON-CO₂ IMPACTS OF AVIATION IS POSSIBLE BUT BEING RESISTED.

Apart from the needed reduction in flights, it is also possible to eliminate or reduce some of aviation’s non-CO₂ contributions to global heating through operational or technological improvements:

- Research shows that a lot of contrail formation could be avoided by adapting flight trajectories to meteorological conditions and avoiding night flights. The benefit on climate would be immediate. The small CO₂ fuel burn penalty that might result could be addressed by stronger measures to reduce CO₂ emissions overall.

- The adoption of lean-burn engine technology already available could reduce CO₂ while further reducing NOx emissions.

- Limiting soot emissions from aircraft engines can reduce the formation of contrails and induced cirrus.

The mitigation of CO₂ remains, of course, essential too.

WHAT NEEDS TO BE DONE

1. Non-CO₂ impacts have to be fully accounted for by the industry, by institutions and governmental bodies and by UNFCCC within the framework of the Paris Agreement.

2. Known measures to mitigate non-CO₂ impacts, such as contrail avoidance and the adoption of lean-burn low NOx engines, must be pursued immediately in addition to CO₂ mitigation.

3. Research and development of operational and technological improvements that give the reduction of non-CO₂ impacts as much importance as those of CO₂ must be intensified and funded.

4. Air traffic must not be allowed to return to pre-Covid-levels. Accordingly, bailouts, subsidies, tax exemptions, and the construction and expansion of airports must cease. Governmental measures for a deep, sustained reduction of flights and for substituting alternatives like rail travel and renewably-powered ships must be quickly implemented.

END NOTES & LITERATURE

1 Bill Hemmings (2019): Why is aviation’s true climate impact being kept under the radar?: https://www.transportenvironment.org/newsroom/blog/why-aviation%E2%80%99s-true-climate-impact-being-kept-under-radar

3 Radiative forcing is directly related to the temperature response of the atmosphere.

4 See Lee et al., footnote 2, Abstract

5 GWP*: method: see Lee et al., footnote 2, 6. Emission equivalency metrics

7 Lee et al., footnote 2 (2. Global aviation growth) estimate that current (2018) CO₂ emissions from aviation represent approximately 2.4% of anthropogenic emissions of CO₂ (including land use change). In addition to this, upstream CO₂ emissions related to the production and distribution of jet fuel (WTT = Well to tank) amount to about 20% of the CO₂ resulting from its combustion (The emission factor used for scope 3 reporting is +20% in France and +21% in the UK: http://www.bilans-ges.ademe.fr/ https://www.gov.uk/government/publications/greenhouse-gas-reporting-conversion-factors-2018)

8 This ratio of 5.9% should not be confused with the 3.5% quoted above. They are different: the latter measures the contribution of aviation to the global heating we observe today extending back to account for all climate pollutants under ambitious mitigation: https://www.nature.com/articles/s41612-018-0026-8, Fig 2)

9 Boeing CEO (2017): Over 80% of the world has never taken a flight. We’re leveraging that for growth: https://www.cnbc.com/2017/12/07/boeing-ceo-80-percent-of-people-never-flown-for-us-that-means-growth.html

11 In 2018 there were 67 Gt of CO₂ equivalent of non-CO₂ short-lived components above our heads, i.e. twice the quantity of CO₂ emitted by aviation since 1940 (According to Lee et al., footnote 2, the net ERF of non-CO₂ terms was 66.6 mW/m² in 2018 and 1 mW/m² is equivalent to 1 Gt CO₂).
